Multiple Linear Regression with sklearn - Exercise Solution

You are given a real estate dataset.

Real estate is one of those examples that every regression course goes through as it is extremely easy to understand and there is a (almost always) certain causal relationship to be found.

The data is located in the file: 'real estate price size year.csv'.

You are expected to create a multiple linear regression (similar to the one in the lecture), using the new data.

Apart from that, please:

- Display the intercept and coefficient(s)
- Find the R-squared and Adjusted R-squared
- · Compare the R-squared and the Adjusted R-squared
- Compare the R-squared of this regression and the simple linear regression where only 'size'
 was used
- Using the model make a prediction about an apartment with size 750 sq.ft. from 2009
- Find the univariate (or multivariate if you wish see the article) p-values of the two variables. What can you say about them?
- · Create a summary table with your findings

In this exercise, the dependent variable is 'price', while the independent variables are 'size' and 'year'.

Good luck!

Import the relevant libraries

Load the data

```
In [2]:
               data = pd.read csv('real estate price size year.csv')
               data.head()
Out[2]:
                   price
                            size
                                  year
             234314.144
                          643.09 2015
             228581.528
                                 2009
                          656.22
             281626.336
                          487.29
                                 2018
             401255.608
                        1504.75 2015
             458674.256 1275.46 2009
               data.describe()
In [3]:
Out[3]:
                          price
                                        size
                                                    year

                 500681.128000 1842.510000 2018.000000
```

Create the regression

Declare the dependent and the independent variables

Regression

```
In [5]: 1 reg = LinearRegression()
2 reg.fit(x,y)

Out[5]: LinearRegression(copy X=True, fit intercept=True, n jobs=1, normalize=False)
```

Find the intercept

```
In [6]: 1 reg.intercept_
Out[6]: -5772267.01746328
```

Find the coefficients

```
In [7]: 1 reg.coef_
Out[7]: array([ 227.70085401, 2916.78532684])
```

Calculate the R-squared

```
In [8]: 1 reg.score(x,y)
Out[8]: 0.7764803683276792
```

Calculate the Adjusted R-squared

Out[10]: 0.7718717161282499

Compare the R-squared and the Adjusted R-squared

It seems the R-squared is only slightly larger than the Adjusted R-squared, implying that we were not penalized a lot for the inclusion of 2 independent variables.

Compare the Adjusted R-squared with the R-squared of the simple linear regression

Comparing the Adjusted R-squared with the R-squared of the simple linear regression (when only 'size' was used - a couple of lectures ago), we realize that 'Year' is not bringing too much value to the result.

Making predictions

Find the predicted price of an apartment that has a size of 750 sq.ft. from 2009.

```
In [11]:    1 reg.predict([[750,2009]])
Out[11]: array([258330.34465995])
```

Calculate the univariate p-values of the variables

Create a summary table with your findings

```
In [16]: 1    reg_summary = pd.DataFrame(data = x.columns.values, columns=['Features'])
2    reg_summary ['Coefficients'] = reg.coef_
3    reg_summary ['p-values'] = p_values.round(3)
4    reg_summary
```

```
        Out[16]:
        Features
        Coefficients
        p-values

        0
        size
        227.700854
        0.000

        1
        year
        2916.785327
        0.357
```

It seems that 'Year' is not event significant, therefore we should remove it from the model.
